

Subroutines are a way of managing and organising programs in a structured way. This allows us to break up programs into smaller chunks. Can make the code more modular and more easy to read as each function performs a specific task.

Procedures are subroutines that do not return values

Functions are subroutines that have both input and output and **return values**

Variable is an **identifier / name** of a **memory location** used to store data that can change during runtime

Constant is an identifier / name of a memory location used to store data, that that remains unchanged for the duration of the program.

Passing by Value

A copy of the value is passed to the subroutine and discarded at the end. Its value outside of the subroutine remains unaffected.

Passing by Reference

Address of parameter is given to the subroutine. Value of the parameter will be updated at the given address.

GLOBAL globalMultiplier = 2 // A global variable used for modifying results

```
PROCEDURE calculateArea(length, width)
  area = length * width // Local variable for area calculation
  print( "Inside CalculateArea:")
  print( "Length: ", length)
  print( "Width: ", width)
  print( "Area: ", area)
END PROCEDURE
```

```
FUNCTION doubleArea(originalArea)
  doubled = originalArea * global Multiplier // Uses global variable
  print( "Doubled Area: ", doubled)
  return doubled
END FUNCTION
```

```
// Main program
print( "Inside Main Program:")
```

```
length = float(input())
width = float(input())
```

```
calculateArea(length, width)
print(caluculatedArea)
doubledResult = doubleArea(areaResult)
print(doubledResult)
```

Parameter – An item of data that is passed to a subroutine when it is called and is used as a variable within the subroutine.

Arguments – The values assigned to parameters when a subroutine is called.

Scope of variables

Scope is the section of code in which the variable can be accessed

A local variable within a subroutine takes can only be accessed within the subroutine, whereas global variables can be accessed across the whole program.

Local Variables:

- Only work inside the subroutine where they are created.
- Deleted when the subroutine finishes.
- Keep subroutines independent and organized.

Global Variables:

- Can be used anywhere in the program.
- Helpful for shared values.
- Risk of accidental changes.
- Stay in memory until the program ends, using more space.

Data Types – determines what value a variable can hold and the operation that can be performed on a variable

Integer	age = 12	A whole number
Float (real)	height = 1.52	A number with a decimal point
Character	a = 'a'	A single letter, number or symbol
String	name = "Bart"	Multiple characters
Boolean	a = True b = False	Has two values; true or false

Sequence:

Sequencing represents a set of steps. Each line of code will have some operation and these operations will be carried out in order line-by-line

Selection

Represents a decision in the code according to some condition. The condition is met then the block of code is executed otherwise it is not. Often alternative blocks of code are executed according to some condition.

If statement		Swich Case Statement
Pseudocode	Python	
entry = input("Enter day of the week: ") if entry=="a" then print("You selected A") elseif entry=="b" then print("You selected B") else print("Unrecognised selection") endif	entry = input("Enter day of the week: ") if entry=="a": print("You selected A") elif entry=="b": print("You selected B") else: print("Unrecognised selection")	entry = input("Enter day of the week: ") switch entry: case "A": print("You selected A") case "B": print("You selected B") default: print("Unrecognised selection") endswitch Not supported in python

Iteration

Iteration Do a set of statements multiple times. Iteration is either '**count controlled**' or '**condition controlled**'.

- Count repeats the section n times,
- Condition waits until a condition has been met before stopping iteration

Count Controlled	While – (Condition Controlled)	do until Loop (Condition Controlled)																																																															
Execute a sequence of statements multiple times <table><tr><td>Pseudocode</td><td>Python</td></tr><tr><td>for i=0 to 7 print(“Hello”) next i</td><td>for i in range(8): print(“Hello”)</td></tr><tr><td colspan="2">Will print hello 8 times (0-7inclusive).</td></tr></table>	Pseudocode	Python	for i=0 to 7 print(“Hello”) next i	for i in range(8): print(“Hello”)	Will print hello 8 times (0-7inclusive).		Repeats a statement or group of statements while a given condition is true. It tests the condition before executing the loop body.	Like a while statement, except that it tests the condition at the end of the loop body.																																																									
	Pseudocode	Python																																																															
	for i=0 to 7 print(“Hello”) next i	for i in range(8): print(“Hello”)																																																															
	Will print hello 8 times (0-7inclusive).																																																																
	<table><tr><td>Pseudocode</td><td></td></tr><tr><td>while answer!="computer" answer=input(“What is the password?”) endwhile</td><td></td></tr></table>	Pseudocode		while answer!="computer" answer=input(“What is the password?”) endwhile		<table><tr><td>Pseudocode</td><td>do answer=input(“What is the password?”) until answer=="computer"</td><td>Python</td></tr><tr><td></td><td></td><td>Not supported in python</td></tr></table>	Pseudocode	do answer=input(“What is the password?”) until answer=="computer"	Python			Not supported in python																																																					
Pseudocode																																																																	
while answer!="computer" answer=input(“What is the password?”) endwhile																																																																	
Pseudocode	do answer=input(“What is the password?”) until answer=="computer"	Python																																																															
		Not supported in python																																																															
	<table><tr><td>Python</td></tr><tr><td>while answer!="computer": answer=input(“What is the password?”)</td></tr></table>	Python	while answer!="computer": answer=input(“What is the password?”)																																																														
Python																																																																	
while answer!="computer": answer=input(“What is the password?”)

Less than or equal to	<=	≤	7<=2	-> False																																																													
Greater than or equal to	>=	≥	7>=2	-> True																																																													

Exam style question

Sally is a classroom teacher. She would like a program to be able to organise where students will sit in her classroom.
A plan of her classroom is shown **here**.

```
01 procedure checkPassword()
02     correctPassword = "ComputerScience12"
03     check = false
04     while check == false
05         enteredPassword = input("Enter Password")
06         if enteredPassword == correctPassword then
07             check = true
08         endif
09     endwhile
10 endprocedure
```

1. Identify the programming construct used on lines 06 to 08 in the procedure checkPassword.

Selection

2. Sally has used a while loop on line 04 of the procedure checkPassword.

Explain why Sally has used a while loop instead of a for loop. [2]

- The number of user attempts is not known
- The code will need to continue until the password entered is correct
- A while loop will keep repeating until the correct password has been input // condition is met
- A for loop will only repeat a certain number of times
- A for loop may continually ask for password even though it's been entered correctly

3. Sally could have used a do until loop instead of a while loop.

Rewrite lines 04 to 09 of the procedure checkPassword using a do until loop instead of a while loop.

```
do
    enteredPassword=input("Enter Password")
    if enteredPassword == correctPassword then
        check = true
    endif
until check == true
```

- Correct use of do at the start of the loop.
- Correct use of until at the end of the loop.
- Correct logic for inputting password, checking the entered password and for setting check to true/checking the password within the condition of the loop.

A function, toBinary(), is needed to calculate the binary value of a denary integer between 0 and 255.

- toBinary() needs to:
- take an integer value as a parameter
 - divide the number by 2 repeatedly, storing a 1 if it has a remainder and a 0 if it doesn't
 - combine the remainder values (first to last running right to left) to create the binary number
 - return the binary number.

For example, to convert 25 to a binary number the steps are as follows:

25 / 2 = 12	remainder 1
12 / 2 = 6	remainder 0
6 / 2 = 3	remainder 0
3 / 2 = 1	remainder 1
1 / 2 = 0	remainder 1

return value = 11001
Write the function toBinary().

You should write your function using pseudocode or program code. [6]

- [1] **Answer:** 1 mark per bullet to max 6
- function header taking parameter
 - looping appropriately e.g. until value is 0
 - dividing by 2 and finding remainder e.g. MOD
 - adding 1 or 0 correctly
 - ...appending to a value to be returned // final string reversed
 - reducing value to use within loop
 - returning calculated value

[3]

Pseudocode	Python
<pre>function toBinary(denary) binaryValue="" while denary > 0 temp = denary MOD 2 if temp == 1 then binaryValue = "1" + binaryValue else binaryValue = "0" + binaryValue endif denary = denary DIV 2 endwhile return binaryValue endfunction</pre>	<pre>def toBinary(denary): binaryValue="" while denary > 0: temp = denary % 2 if temp == 1: binaryValue = "1" + binaryValue else: binaryValue = "0" + binaryValue denary = denary // 2 return binaryValue</pre>

Row 1	5	6	7	8																		
Row 2	9	10	11	12																		

Exam style question

A 2-dimensional (2D) array, data, holds numeric data that Karl has entered. The declaration for the array is:

array data[16,11]

The array data, has 16 'rows' and 11 'columns'.

This is an extract from data:

	0	1	2	3	...	10
0	1	5	7	12	...	36
1	3	4	15	16	...	48
2	0	0	1	3	...	10
3	12	16	18	23	...	100
...
15	6	10	15	25	...	96

The data in each 'row' is in ascending numerical order.

Karl needs to analyse the data.

Karl needs to find the mean average of each 'column' of the array. The mean is calculated by adding together the numbers in the column, and dividing by the quantity of numbers in the column.

1	5	7	12
3	4	15	16
0	0	1	3
12	16	18	23

For example, the first 'column' mean would be: (1+3+0+12)/4 = 4

Write an algorithm to output the mean value of each 'column' in the array data. [5]

1 mark per bullet

- Looping through each column [1]
- Looping through each row [1]
- ...Adding to a total [1]
- ...Calculating average correctly [1]
- Outputting average [1]

OCR Pseudocode	Using in range
<pre>for y =0 to 10 total = 0 for x = 0 to 10 for x = 0 to 15 total = total + data[x,y] next x print(total/16) next y</pre>	<pre>for y in range (11): total = 0 for x in range(16): total = total + data[x,y] print(total/16)</pre>

A card game uses a set of 52 standard playing cards. There are four suits; hearts, diamonds, clubs and spades. Each suit has a card with a number from; 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13.

The card game randomly gives 2 players 7 cards each. The unallocated cards become known as the deck.

The players then take it in turns to turn over a card. A valid move is a card of the same suit or the same number as the last card played.

The winner is the first player to play all of their cards.

The cards are held in the 2D array cards. The first index stores the card number and the second index stores the suit, both as strings.

Write a **pseudocode statement** or program code to declare the array cards.

array cards[7, 4] or array towns [3,8]

Records

A record is a data structure that groups together related items of data
You can store more than one type of data together
A record is an unordered data structure
Can have multiple instances

Player records:

Player1 record

Olivia
35

Player 2 record

Luke
40

Creating a record structure

recordStructure recordstructurename

 fieldname : datatype

...

endRecordStructure

The pseudocode to define a new complex data structure called player:

```
RECORD player
  name: String
  score: int
ENDRECORD
```

Adding data to the record

recordidentifier : recordstructurename
recordidentifier.fieldname = data

The pseudocode to define a new complex data structure called Player:

```
Player1: player
Player1.player.name = 'Olivia'
Player1.player.score = 35
```

Array of Records

Records are treated as **data types**, so they can be held within a single **array**.

This allows for storage of more than one **record** within the same structure. This structure is essentially an **array of records**.

The table below simplifies the way that this data would be held in memory.

- The records for the players could be stored in a 1D array.
- It allows easy access/indexing/manipulation of each data item in turn
- 1D Array can hold multiple items of same data type – record
- Maximum number of array elements is known

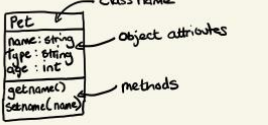

0	1	2	3
Olivia 35	Luke 40	Adam 25	Alex 35

Pseudocode of Arrays of records:

Players(100) As player

We can then reference any element of the array:

Players(3).name = “Jane”

	Record	Class
Similarities		
Data structure	A record is a data structure that stores data together, organised by attributes.	A <i>class</i> is a record with associated methods. Each object is a data structure with attributes stored together
Set up in advance	Attributes and structure for the record are set up. Meaning that it is created by the programmer for a particular purpose.	Constructor method defines the class object
Store data of different types	recordStructure pets name : String type : String age : Int endRecordStructure	
Both can have multiple instances	Yes	Yes
Accessed by their names	Yes	Yes
Differences		
Class also has methods Class can include visibility of properties / private		

Working with strings

Strings		
Get length of a string	len("Hello")	
Character to character code	asc("a")	
Character code to character	CHR(101)	
String to integer	a=INT("12")	
String to float	a=FLOAT("12.3")	
integer to string	a=STR(12)	
real to string	a=STR(12.3)	
substrings - select parts of a string		
Example	student="Harry Potter"	
Output the first two characters	print(student[0:2])	Ha
Output the first three characters	print(student[:3])	Har
Output characters 2-4	print(student[2:5])	Rry
Output the last 3 characters	print(student[-3:])	Ter
Output a middle set of characters	print(student[4:-3])	y Pot
*A negative value is taken from the end of the string.		

Exam style Question <p>The function validate Answer takes in the randomLetters as an array of letters and the player's answer as a string. It then checks if the word the player has entered only contains letters from the 10 random letters with each letter being used only once. (At this stage the program doesn't check if the answer provided is an actual word.) It then returns a score, out of 10, for a valid word or 0 for an invalid word.</p> <p>Example:</p> <p>If the random letters are: OPXCMURETN</p> <p>The word COMPUTER returns 8</p> <p>Whereas</p> <p>The word POST returns 0 (there is no S in the random letters).</p> <p>The word RETURN returns 0 (there is only one R in the random letters).</p> <p>Complete the function validateAnswer</p> <p>function validateAnswer(answer, randomLetters[]) [6]</p>	Mark scheme <ul style="list-style-type: none">- Function traverses every letter of answer (1)- Function traverses every randomLetters (1)- Correctly checks each letter of answer against each of randomLetters (1)- Returns 0 if answer contains a letter that doesn't occur in randomLetters (1)- Returns 0 if letter occurs more times in answer than randomLetters (1)- Returns answer length for a valid word.(1) <p>Solution:</p> <pre>function validateAnswer(answer, randomLetters) valid = True score = 0 lengthAnswer = len(answer) lengthRandom = len(randomLetters) index = 0 while (valid == True) and (index < lengthAnswer) numChar = 0 # Initialise numChar for each letter currentLetter = answer[index:1] for i = 1 to lengthRandom-1 if currentLetter == randomLetters[i] numChar = numChar + 1 # If the letter does not exist in randomLetters list if numChar == 0 valid = False index = index + 1 # Move to the next letter in answer # If all letters pass check, answer is valid if valid == True score = lengthAnswer return score print(validateAnswer("POST", "OPXCMURETN"))</pre>
---	--

Working with files

Open file Whatever we are doing to a file whether we are reading, writing or adding to or modifying a file we first need to open it using:

```
open(filename,access_mode)
```

There are a range of access mode depending on what we want to do to the file, the principal ones are given below:

Access Mode	Description
r	Opens a file for reading only
w	Opens a file for writing only. Create a new file if one does not exist. Overwrites file if it already exists.
a	Append to the end of a file. Create a new file if one does not exist.

Reading text files

read – Reads in the whole file into a single string	f=open("file.txt","r") print(f.read()) f.close()
readline – Reads in each line one at a time	f=open("file.txt","r") print(f.readline()) print(f.readline()) print(f.readline()) f.close()
readlines – Reads in the whole file into a list	f=open("file.txt","r") print(f.readlines()) f.close()

Writing text files

Write in single lines at a time	file=open("days.txt",'w') file.write("Monday\n") file.write("Tuesday\n") file.write("Wednesday\n") file.close()
Write in a list	say=["How\n","are\n","you\n"] file=open("say.txt",'w') file.writelines(say) file.close()

Exam style Question

Albert runs a competition each week in his local village hall. So that Albert can contact the winner he would like a program for the winner to enter their telephone number which is then checked and written into a text file.

The rules for Albert's program are as follows:

- 1. The telephone number is entered. This is checked to ensure that the first digit is a 0
- 2. If the first digit is not a 0 then a message saying “Needs To Start With 0” is printed
- 3. If the first digit is a 0 then the telephone number is passed into a pre-existing function called checkLength as a parameter. This will return true if the length of the telephone number is long enough
- 4. If the telephone number is long enough then it is written into a text file called "winner.txt"
- 5. If the telephone number is not long enough then a message saying “Not Long Enough” is printed.

Complete the procedure competitionWinner so that it meets the rules of Albert's program.

You should write your procedure using pseudocode or program code.

```
procedure competitionWinner() [5]

    telNum = input("Enter Telephone Number")
    if telNum[0] == "0" then
        length = checkLength(telNum)
        if length == true then
            myfile = openWrite("winner.txt")
            myfile.write(telNum, 'w')
            myfile.close()
        else
            print ("Not Long Enough")
        endif
    else
        print ("Needs To Start With 0")
    endif

Endprocedure
```

Answer: 1 mark per bullet up to a maximum of 5 marks, e.g.:

- Suitable logic for inputting the telephone number
- Suitable logic for ensuring the telephone number starts with a 0
- Suitable logic for passing the telephone number into the function checkLength
- If true, suitable logic for opening and closing winner.txt
- ...suitable logic for writing the telephone number to winner.txt
- Suitable logic for printing “Needs To Start With 0” and "Not Long Enough"

Recursive algorithms

Recursion

When a subroutine calls itself during execution.
Continues until a stopping condition is met.
(Base Case)

Recursion produces the same result as iteration, but is more suited to certain problems which are more easily expressed using recursion.

Example

A common example of a naturally recursive function is **factorial**, shown below:

- The Factorial of a positive integer, n, is defined as the product of the sequence n, n-1, n-2,
- The factorial of a number is the product of all the integers from 1 to that number.
- For example, the factorial of 3 (denoted as 3!) is 1*2*3= 6
- Factorial is not defined for negative numbers and the factorial of zero is one, 0! = 1

Iterative Solution

Function factorial(number):
 factorial = 1
 # loop from the number till 1
 for number in range(number, 1,-1):
 # multiply current number with the product of previous numbers
 factorial = factorial * number
 return factorial

Recursive Solution

```
function factorial(number)
    if number == 0 or 1 then #base case
        return 1
    else:
        return number * factorial(number - 1);
    endif
end function
```

Example: Trace code where n=3

Call	n	Return	
factorial(3)	3	6	3*(Factorial (2))
factorial(2)	2	2	2 * (factorial (1))
factorial(1)	1	1	1 *(factorial(0))
factorial (0)	0		

Final answer **6**

Each time the function calls itself, a new stack frame is created within the call stack , where parameters , local variables and return addresses are stored.

Benefit

- **Easier to read and understand** – The logic often follows the problem's natural structure.
- **Concise and quick to write** – Requires fewer lines of code than iterative solutions.
- **Ideal for specific problems** – Particularly useful for tree structures and divide-and-conquer algorithms.
- **Breaks problems into smaller parts** – Each recursive call simplifies the problem step by step.

Drawbacks of Recursion:

- **Risk of stack overflow** – Too many recursive calls can exceed memory limits, causing a crash.
- **Requires a well-defined base case** – Without a proper stopping condition, recursion can lead to infinite loops.
- **Harder to trace and debug** – Each call has its own set of variables, making execution more complex to follow.
- **Higher memory consumption** – Recursive calls store additional data on the stack, using more memory than iteration.
- **Often slower than iteration** – Maintaining the call stack adds extra processing overhead.

Exam Style Questions

- Re-write an iterative algorithm into a recursive algorithm (vice versa)
- Discuss the benefits and drawbacks of recursive algorithms compared to iterative algorithms.

<p>High Level Programming Languages</p> <ul style="list-style-type: none"> • Much easier to learn, write and debug. • Examples include Python, Java and C • Code written in these languages must be translated to machine code before it can be executed. <p>Advantages</p> <ul style="list-style-type: none"> • Much more widely understood and used. • Easier to learn, code in and understand. • Much quicker to produce usable code. • More support and learning resources are available. • Easier to debug and find issues <p>Disadvantages</p> <ul style="list-style-type: none"> • Less flexible. • Must be translated before being executed • Very difficult to write and understand. • Much more time consuming to produce code. 	<p>Test data</p> <p>Code needs to be tested with a range of different input data to ensure that it works as expected under all situations. Data entered need to be checked to ensure that the input values are:</p> <ul style="list-style-type: none"> • within a certain range • in correct format • the correct length • The correct data type (eg float, integer, string) <p>The program is tested using normal, erroneous or boundary data.</p> <p>Normal data - Data that we would normally expect to be entered. For example for the age of secondary school pupils we would expect integer values ranging from 11 to 19.</p> <p>Erroneous data - Data that are input that are clearly wrong. For instance, if some entered 40 for the age of a school pupil. The program should identify this as invalid data but at the same time should be able to handle this sensibly which returns a sensible message and the program does not crash.</p> <p>Boundary data - Data that are on the edge of what we might expect. For instance if someone entered their age as 10, 11, 19 or 20.</p>
<p>Programming Standards</p> <ul style="list-style-type: none"> • No function may be longer than a single page of code: this is to reduce complexity and aid readability. • Variable identifiers must conform to a standard convention: this helps others to understand the code and reduces the likelihood of duplication, makes maintenance easier. • Each function must have a single entry point: this reduces complexity and makes the search for any bugs more straightforward. • Variables must not be set up outside the scope of a function: this sets a limit on where to look for bugs and reduces the likelihood of a problem spread across many modules. • Indentation • Global variables – use upper case UPPER_CASE_WITH_UNDERSCORES • In python - function names should be lowercase • Comment your code - Do not do line-by-line comments - makes the code look almost unreadable 	<p>Debugging</p> <p>Syntax errors – Errors in the code that mean the program will not even run at all. Normally this is things like missing brackets, spelling mistakes and other typos.</p> <p>Runtime errors – Errors during the running of the program. This might be because the program is writing to a memory location that does not exist for instance. eg. An array index value that does not exist.</p> <p>Logical errors - The program runs to termination, but the output is not what is expected. Often these are arithmetic errors.</p>

IDE and Debugging

Source code editor

The editor aims to make the coding process easier by providing features such as autocompletion of words, indentation, syntax highlighting,

Programming Techniques KO
A programmer uses an Integrated Development Environment (IDE).

Identifying **and** describing **three** IDE features that can help the programmer to develop or debug a program.

[6]

Syntax highlighting... to identify keywords, variables and help identify syntax errors

Breakpoints...stop a program running at a point to check variables

```
example.py
1 def add_numbers(a, b):
2     """This function adds two numbers and returns the result."""
3     result = a + b
4     print("The result is ", result)
5
6 def multiply_numbers(a, b):
7     """This function multiplies two numbers and returns the result."""
8     result = a * b
9     print("The result is ", result)
10
11 # Main program
12 num1 = float(input("Enter first number: "))
13 num2 = input("Enter second number: ")
14
15 # Call the subroutines
16 sum_result = add_numbers(num1, num2)
17 product_result = multiply_numbers(num1, num2)
```

```
Shell
%Run example.py
Enter first number: 23
Enter second number: 43
Traceback (most recent call last):

    sum_result = add_numbers(num1, num2)
  File "/Users/elizabethallgar/Library/CloudStorage/OneDrive-KingJames'sSchool/example.py", line 3, in add_numbers
    result = a + b
TypeError: unsupported operand type(s) for +: 'float' and 'str'
>>>
```

Error diagnostics... to locate and fix errors

Auto-complete... start typing a command/identifier and it completes it

rand_number = random.

choice
getrandbits
randint
random
randrange
seed
uniform

Variable watch window...view how variables change while the program executes

Variables	
Name	Value
add_numbers	<function add_numbers at 0x1012e6cb0>
multiply_numbers	<function multiply_numbers at 0x10133ce50>
num1	23.0
num2	'43'

Stepping / step through... run the program line by line to check variable values at each stage

```
example.py
1 def add_numbers(a, b):
2     """This function adds two numbers and returns the result."""
3     result = a + b
4     print("The result is ", result)
5
6 def multiply_numbers(a, b):
7     """This function multiplies two numbers and returns the result."""
8     result = a * b
9     print("The result is ", result)
10
11 # Main program
12 num1 = float(input("Enter first number: "))
13 num2 = float(input("Enter second number: "))
14
15 # Call the subroutines
16 sum_result = add_numbers(23.0, 12.0)
17 product_result = multiply_numbers(num1, num2)
18
```
